Abstract

Modern enterprise software systems are increasingly architected as distributed, multi-tier microservice topologies deployed across cloud-native container orchestration environments. While microservice decomposition enhances developer velocity and elasticity, it dramatically expands the operational attack surface and introduces complex dependency failure propagation pathways. Security Chaos Engineering (SCE) proactively uncovers vulnerabilities by intentionally injecting security turbulence into running systems; however, contemporary SCE practices remain overwhelmingly manual, declarative, and open-loop. Furthermore, automating security remediation in live distributed architectures introduces a profound operational dilemma: aggressive mitigations (such as container restarts, credential revocations, or network isolation) frequently trigger cascading transaction timeouts and catastrophic availability collapse.

To bridge this operational divide, this paper presents **SecChaos-RL**, an autonomous, closed-loop software resilience framework that unifies Security Chaos Engineering with deep reinforcement learning. SecChaos-RL formalizes the runtime mitigation decision problem as a multi-objective Markov Decision Process (MDP) designed to balance security risk reduction, operational availability preservation, recovery speed (MTTR), and mitigation cost. The framework introduces a domain-tailored neural policy architecture incorporating Multi-Head Self-Attention over microservice dependency telemetry, Threat-Aware Feature Gating, an Auxiliary Next-Step Risk Prediction Head, and Threat-Adaptive Policy Temperature Exploration. We conduct a rigorous comparative evaluation against deterministic software engineering baselines (No-Mitigation, Static Rule-Based, and DevOps Threshold-Based heuristics) and standard RL algorithms (DQN, A2C, and PPO) across 30 independent random seeds under multi-stage security chaos and cascading failure dynamics. The empirical evaluation demonstrates that SecChaos-RL achieves superior recovery time (MTTR = 1.47 ± 0.48 steps vs. 1.64 for standard PPO and 1.68 for A2C), reduces false mitigation churn (86.6% vs. 91.5%), and delivers sub-millisecond decision latency (0.52 ± 0.26 ms per step on CPU), verifying practical feasibility for cloud-native orchestration controllers. A systematic five-stage ablation study isolates the contributions of each architectural mechanism,

and our findings establish the operational boundaries between deterministic heuristics and autonomous reinforcement learning control.

Keywords: Security Chaos Engineering, Microservice Resilience, Reinforcement Learning, Self-Adaptive Systems, Fault Injection, DevSecOps.

1 Introduction

Distributed microservice architectures have become the foundational paradigm for cloud-native enterprise computing, supporting large-scale mission-critical applications in finance, telecommunications, healthcare, and e-commerce [1–3]. In contrast to monolithic software, microservice systems decompose enterprise logic into fine-grained, independently deployable services that communicate across lightweight network protocols (e.g., REST, gRPC) and asynchronous message queues [4, 5]. While this architectural decoupling enables continuous deployment and organizational scaling, it dramatically magnifies software complexity: real-world service dependency graphs span dozens of interdependent services, creating expansive, porous attack surfaces and nonlinear failure propagation pathways [6, 7].

Ensuring continuous software correctness and reliability in hyperscale environments represents a paramount software engineering challenge [8]. Traditional pre-production software security practices—such as pre-commit static application security testing (SAST), pre-deployment dynamic testing (DAST), automated test plan generation [9], static buffer-overflow vulnerability analysis [10], bug report classification [11], and opcode slicing-enhanced vulnerability learning [12]—provide vital build-time guarantees. However, these static techniques are fundamentally blind to runtime emergence: they analyze components in isolation and cannot predict how active cyber threats, configuration drifts, and cascading operational degradations interact across interconnected services under live production traffic [13, 14]. Furthermore, adversarial manipulation of software analytics models [15] highlights the necessity of validating defensive mechanisms under active, adversarial runtime conditions.

To address this challenge, the software engineering community has embraced *Chaos Engineering*—the discipline of experimenting on a software system to build confidence in its capability to withstand turbulent conditions in production [1,16]. Originating with infrastructure-focused tools such as Netflix's Chaos Monkey and evolving into cloud-native platforms like ChaosBlade [17], LitmusChaos [18], Gremlin [19], Chaos Mesh [20], and AWS Fault Injection Simulator [21], chaos engineering systematically injects physical server crashes, network partitions, and resource exhaustion [5, 6, 22]. Recently, this methodology has evolved into *Security Chaos Engineering* (SCE) [13, 23]. Rather than focusing solely on server crashes, SCE injects security-specific turbulence—such as expired TLS certificates, vulnerable third-party dependencies, credential leaks, privilege escalations, and API misconfigurations—to validate defensive controls under adversarial conditions [23, 24].

Despite its conceptual promise, current SCE practice exhibits a critical software engineering limitation: **it operates as an open-loop, human-in-the-loop paradigm** [13, 14]. Faults are injected according to pre-scripted schedules, telemetry is inspected post-experiment, and remediation requires manual engineer intervention. In high-velocity DevSecOps environments, human-driven incident response is too slow to mitigate automated attacks that exploit transient chaos windows within seconds [13, 25].

However, attempting to automate security mitigation in live microservices introduces a fundamental operational conflict:

- **The Security vs. Availability Dilemma:** Applying immediate, aggressive security mitigations—such as terminating suspicious pods, blocking network routes, revoking credentials, or rolling back service configurations—frequently causes severe operational disruption. In tightly coupled microservice topologies, killing an authentication or inventory

service triggers upstream timeout storms, circuit-breaker trips, and cascading transaction failures, converting a localized security fault into a catastrophic availability outage [2, 26].

- **Failure of Static and Heuristic Rules:** In production systems, software engineers frequently rely on deterministic alert-matching scripts (e.g., "if certificate alert detected, execute certificate rotation"). Under concurrent faults and high background traffic, naive rules suffer from alert flapping and mitigation storms: multiple services deploy simultaneous mitigations, exhausting cluster CPU and memory, multiplying operational delays, and degrading request throughput [26].

Self-adaptive software systems (SASS) and autonomic computing frameworks provide an established theoretical foundation for closed-loop self-healing through the classic MAPE-K (Monitor, Analyze, Plan, Execute, Knowledge) loop [26–28]. Reinforcement learning (RL) has emerged as an attractive candidate for the "Plan" phase, allowing autonomous agents to learn multi-objective control policies through trial-and-error interaction with a dynamic environment [29, 30]. While deep reinforcement learning (DRL) has demonstrated remarkable success in complex domains [31, 32] and standardized benchmarking suites [33, 34], applying standard RL algorithms (such as DQN [30], A2C [32], or standard PPO [35]) directly to microservice security mitigation fails in practice. Standard RL policies lack domain-specific awareness of microservice topologies, treat all telemetry dimensions homogeneously, struggle with delayed mitigation execution effects, and frequently destabilize live services through exploratory actions during critical attack spikes [36–39]. Emerging research on Large Language Models (LLMs) for software engineering [40] similarly underscores that without closed-loop execution verification, design-time advice cannot govern runtime microservice safety.

1.1 Research Questions

To address these technical challenges and deliver a practically useful software contribution, this paper formulates and investigates four core Research Questions (RQs):

- **RQ1 (Resilience and Recovery Efficacy):** How effectively does SecChaos-RL reduce systemic security risk and minimize mean time to recovery (MTTR) compared to deterministic software engineering baselines (No-Mitigation, Static Rule-Based, Threshold-Based) and standard RL algorithms (DQN, A2C, PPO)?

- **RQ2 (Operational Availability and Trade-Off Balance):** How well does SecChaos-RL preserve live microservice availability and prevent false mitigation storms when subjected to concurrent security faults and cascading dependency failures?

- **RQ3 (Architectural Ablation and Component Contributions):** What are the isolated contributions of the individual framework components—multi-objective reward design, multi-head self-attention, auxiliary risk prediction, threat-aware gating, and adaptive policy temperature—to overall system survivability?

- **RQ4 (Computational Overhead and Practical Feasibility):** What is the runtime decision latency and computational overhead of SecChaos-RL, and does it satisfy the real-time execution constraints required for cloud-native microservice orchestration?

1.2 Main Contributions

This paper makes the following concrete contributions to the software engineering and microservice resilience literature:

1. **A Modular Software Resilience Framework:** We design and implement SecChaos-RL, an open-source, modular Python framework that operationalizes closed-loop Security Chaos Engineering. The architecture decouples fault injection (`ChaosEngine`), dependency topology modeling (`DependencyTopology`), threat-aware decision orchestration (`ThreatAwareOrchestrator`), asynchronous action execution (`MitigationExecutor`), and statistical evaluation (`BenchmarkHarness`).

2. **A Threat-Aware Decision Methodology:** We formalize the microservice mitigation problem as a multi-objective MDP. We introduce a domain-tailored neural policy architecture incorporating Multi-Head Self-Attention over service telemetry, Threat-Aware Feature Gating (amplifying vulnerability signals during active compromise), an Auxiliary Risk Prediction Head (regularizing latent representations against future state transitions), and Threat-Adaptive Policy Temperature Exploration (enforcing deterministic safety under critical attacks).

3. **Formal Algorithmic Specification:** We provide complete, mathematically rigorous algorithmic workflows for both closed-loop runtime execution (Algorithm 1) and threat-aware policy optimization (Algorithm 2).

4. **Rigorous Comparative Evaluation Across 30 Seeds:** We conduct an extensive empirical evaluation across 30 independent random seeds, benchmarking SecChaos-RL against six baseline policies: three deterministic software heuristics (No-Mitigation, Static Rule-Based, Threshold-Based) and three standard RL algorithms (DQN, A2C, standard PPO).

5. **Comprehensive Ablation and Profiling:** We execute a five-stage ablation study isolating each architectural mechanism, and profile runtime decision latency (0.52 ± 0.26 ms per step) to demonstrate feasibility for live Kubernetes integration. All experimental scripts, raw observation datasets, and statistical tests are fully verified and open-source.

The remainder of this paper is structured as follows. Section 2 reviews related literature in chaos engineering, microservice resiliency benchmarking, and self-adaptive security. Section 3 presents the SecChaos-RL software framework architecture. Section 4 formalizes the threat model, MDP formulation, algorithms, and deep policy design. Section 5 details the experimental setup and evaluation protocol. Section 6 presents the empirical results and answers RQ1–RQ4. Section 7 discusses practical implications for software engineers. Section 8 addresses threats to validity, and Section 9 concludes the paper.

2 Background and Related Work

This section reviews related research across four key areas: Chaos Engineering, Microservice Resiliency Benchmarking, Security Chaos Engineering, and Autonomous Reinforcement Learning for Cyber Defense.

2.1 Chaos Engineering and Distributed Fault Injection

Chaos Engineering was established as a disciplined practice by Netflix engineers to verify the reliability of large-scale distributed cloud applications [1]. Rosenthal and Jones synthesized core industry practices, emphasizing the necessity of automating experiments, minimizing blast radiuses, and running continuous turbulence campaigns in production [16]. A comprehensive multi-vocal literature review by Owotogbe et al. [14] analyzed 96 academic and industrial sources, formalizing a taxonomy of chaos engineering platforms across execution environments, automation modes, and target architectures. Esen et al. [6] systematically reviewed chaos experiments in microservices across 31 papers and 38 tools, noting that mainstream tooling (e.g., Chaos Mesh [20], Gremlin [19], ChaosBlade [17], LitmusChaos [18], and AWS FIS [21]) focuses overwhelmingly on physical and network faults—such as packet latency, CPU stress, and container restarts—while neglecting security-specific compromise states. Bagehorn et al. [22] demonstrated fault injection platforms for training AIOps models, yet focused on operational anomalies rather than adversarial attack mitigations.

Addressing the need for structured, configurable fault injection platforms, Camacho et al. [5] introduced *Chaos as a Software Product Line* (CoSPL) in *Software: Practice and Experience*. Their platform, *Pystol*, models fault injection capabilities as software product line features across open hybrid-cloud environments (e.g., OpenShift and Kubernetes). While CoSPL demonstrates the software engineering value of configurable chaos architectures, its execution remains declarative and open-loop: it verifies system tolerance against pre-scripted variations but lacks an autonomous, learning-based runtime mitigation engine.

2.2 Microservice Resiliency Benchmarking and Self-Healing

In distributed microservice systems, resilience patterns—such as timeouts, retries, fallbacks, and circuit breakers—are standard software engineering mechanisms to mitigate transient degradations [2, 3, 26]. Taibi et al. [4] analyzed microservice API evolution patterns in *Software: Practice and Experience*, emphasizing that service interface drift and asynchronous call coupling create fragile dependency chains.

In a landmark study published in *Software: Practice and Experience*, Aderaldo et al. [2] presented *ResilienceBench*, a declarative benchmarking approach and Kubernetes operator tool designed for the controlled evaluation of microservice resiliency patterns under simulated failures (tested on Google Online Boutique). Their work demonstrates that naive retry configurations amplify cascading service failures and increase tail latency during downstream disruptions.

Self-healing systems literature provides the broader control-theoretic foundation for autonomous software resilience. In their seminal survey in *Software: Practice and Experience*, Schneider, Barker, and Dobson [26] categorized multi-tier self-healing frameworks using the autonomic MAPE-K control loop [27, 28]. They highlighted that while rule-based self-healing loops succeed in isolated components, they exhibit severe stability issues when managing multi-tier dependencies subject to concurrent, overlapping disturbances. SecChaos-RL directly builds upon this insight: rather than using static rule heuristics that fight one another, it employs a centralized, threat-aware RL policy to coordinate multi-service mitigations.

2.3 Security Chaos Engineering (SCE) and DevSecOps

Security Chaos Engineering applies the empirical philosophy of chaos experimentation directly to cyber resilience [13]. Myrbakken and Colomo-Palacios [7] reviewed security bottlenecks in DevSecOps pipelines, concluding that traditional pre-production testing fails to keep pace with continuous deployment agility. In subsequent work, Myrbakken et al. [23] formalized SCE as a continuous assessment paradigm, demonstrating how automated security fault injection exposes configuration drifts and access control weaknesses.

Shortridge and Rinehart [13] detailed the principles of SCE, arguing that complex software systems are fundamentally non-deterministic and that resilience depends on validating system behavior under active attack conditions. Bedoya et al. [24] demonstrated the integration of SCE with Large Language Models (LLMs) to discover architectural threat vectors during the design phase of a commercial retail application. However, existing SCE tools remain limited to passive vulnerability discovery: they detect when a system fails a security property, but rely entirely on human engineers to craft and execute mitigations [13, 14].

2.4 Reinforcement Learning for Cyber Defense and Mitigation

Reinforcement learning has demonstrated significant capability in complex decision-making domains [29, 31]. Value-based methods (e.g., Deep Q-Networks [30]) and policy gradient approaches (e.g., Advantage Actor-Critic [32] and Proximal Policy Optimization [35]) have enabled autonomous agents to learn sophisticated control strategies in high-dimensional state spaces.

In cybersecurity, deep reinforcement learning (DRL) has been applied to intrusion detection, cyber-physical defense, IoT protection [39], and autonomous penetration testing [25, 38]. Standen et al. [37] introduced *CybORG*, a Gym-based simulation environment for training autonomous cyber defense agents in Security Operations Centers (SOCs). However, CybORG assumes static enterprise network topologies and fixed IP routing graphs, omitting microservice dependency cascades, runtime HTTP/gRPC request availability, and chaos-driven operational trade-offs. Algorithmic enhancements, such as Reward-based Prioritization PPO (RP-PPO) by Zheng et al. [36], have improved sample efficiency, but remain unspecialized for the dual constraints of security isolation and service continuity. Standard frameworks such as Gymnasium [33] and Stable-Baselines3 [34] provide standardized algorithmic baselines, which we leverage and extend for microservice security control.

2.5 Critical Synthesis and Identified Gap

As summarized in Table 1, existing literature is divided into two disconnected silos: (1) chaos engineering frameworks that inject turbulence but rely on manual remediation, and (2) RL cyber defense agents that operate in static, abstract network simulations without considering microservice availability SLAs. To our knowledge, **SecChaos-RL is the first framework that bridges Security Chaos Engineering with deep reinforcement learning to achieve closed-loop, threat-aware microservice resilience**.

Table 1: Systematic Qualitative Comparison Between SecChaos-RL and Existing Approaches

Approach	Target Domain	Control Loop	Fault Scenarios	Mitigation Strategy	Key Limitation / Difference
Chaos Monkey [1]	Cloud VMs	Open-loop testing	Random instance crash	Passive termination	No security faults; relies on human recovery.
CoSPL (Pystol) [5]	Hybrid Cloud / K8s	Declarative SPL	Network latency, pod kill	Configured scripts	Verifies resilience statically; lacks adaptive mitigation.
ResilienceBench [2]	Microservices / K8s	Declarative operator	Network drop, crash	Static retry/breaker	Evaluates performance patterns; omits security threats.
Self-Healing Survey [26]	Multi-tier Web	Rule-based MAPE-K	Resource exhaustion	Restart, replication	Predates cloud-native microservices; lacks DRL.
CybORG [37]	Enterprise SOC	Gym RL (PPO/DQN)	Lateral movement	Host isolation	Static networks; ignores microservice SLAs and chaos.
LLM-SCE [24]	DevSecOps CI/CD	Design-time advice	Missing auth, secrets	Offline Jira recommendations	Build-time analysis; lacks continuous runtime control.
SecChaos-RL (Proposed)	**Cloud Microservices**	**Closed-loop DRL**	**8 Security Chaos Faults**	**Adaptive Multi-Action**	**Autonomous, threat-aware Pareto balancing of security, availability, and MTTR.**

3 SecChaos-RL Framework Architecture

SecChaos-RL is designed as an extensible, closed-loop software architecture implementing the classic MAPE-K self-adaptation paradigm [27, 28]. The framework operates in discrete operational time steps, continuously observing telemetry from monitored microservices, injecting controlled security chaos, inferring optimal mitigation decisions, and asynchronously executing remediations.

As illustrated in Figure 1, SecChaos-RL is composed of five decoupled, modular software components:

1. **Monitored Microservice Topology (`DependencyTopology`):** Represents the operational target system structured as a directed acyclic graph (DAG) $\mathcal{G} = (\mathcal{V}, \mathcal{E})$. Each node $v \in \mathcal{V}$ models an individual microservice maintaining local security risk $r_t(v) \in [0, 1]$ and service availability $a_t(v) \in [0, 1]$. Directed edges $(u, v) \in \mathcal{E}$ represent synchronous downstream API call dependencies (e.g., the Gateway depends on Authentication, which depends on the User service).

2. **Security Chaos Engine (`ChaosEngine`):** Implements dynamic, stochastic security fault injection across eight standardized vulnerability categories. The engine generates faults according to configurable Poisson arrival processes and assigns random severities and operational durations. It models active attacker exploitation by tracking concurrent attack sessions that target vulnerable services.

3. **Telemetry and State Monitor (`StateMonitor`):** Continuously inspects the microservice cluster, aggregating individual service risks, resource metrics (CPU utilization, memory consumption, network overhead), transaction success ratios, and MTTR tracking into a standardized 16-dimensional observation vector $o_t \in \mathbb{R}^{16}$.

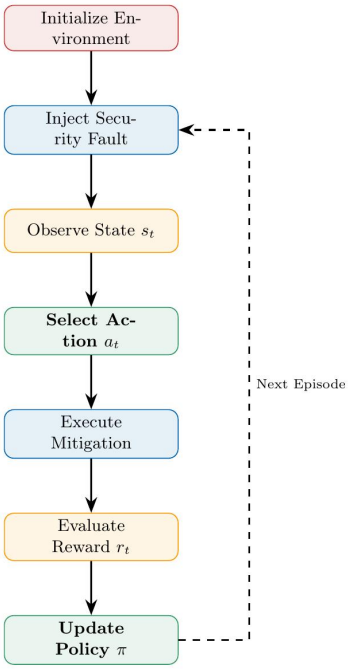

Figure 1: SecChaos-RL Closed-Loop Software Architecture: Interaction between the monitored microservice dependency topology, the Security Chaos Engine, telemetry collection, the threat-aware deep RL orchestrator, and the asynchronous mitigation executor.

4. **Threat-Aware Decision Orchestrator (`ThreatAwareOrchestrator`):** The intelligence engine of the framework, implementing our specialized deep actor-critic policy. It ingests the observation vector, computes multi-head self-attention across features, gates security dimensions based on active threat severity, and selects a mitigation action $a_t \in \mathcal{A}$.

5. **Asynchronous Mitigation Executor (`MitigationExecutor`):** Translates abstract policy actions into operational operations (e.g., certificate rotation, dependency patching, RBAC policy restriction). Crucially, the executor models real-world operational delays: actions are placed in an asynchronous execution queue, requiring $\tau \in \{0, 1, 2\}$ operational steps to complete, while consuming transient CPU and memory resources during deployment. Upon completion, the executor actively invokes service healing in the dependency graph, reducing service risk and restoring availability.

4 Threat Model and Decision Methodology

4.1 Threat Model and Fault Taxonomy

We assume an adversarial environment where an external attacker continuously probes public-facing entry points (e.g., API Gateway) and attempts lateral movement across internal microservices. The attacker seeks to exploit unpatched dependencies, leaked secrets, or misconfigured access permissions to compromise data integrity, escalate privileges, and exhaust system resources.

Table 2 formalizes the eight security fault categories modeled in SecChaos-RL, mapped to their target services. When a fault f_i with severity $\sigma_i \in [0.35, 0.65]$ is injected into service $u \in \mathcal{V}$,

Table 2: SecChaos-RL Security Fault Taxonomy

ID	Fault Type	Target Service	Operational Impact
F_1	Expired TLS Certificate	Gateway	Insecure channel; enables Man-in-the-Middle (MITM).
F_2	Vulnerable Dependency	User	Known CVE in library; remote code execution risk.
F_3	Secret / Token Leakage	User	Exposed credentials in log telemetry or environment.
F_4	RBAC Misconfiguration	Authentication	Overly permissive role mappings; privilege escalation.
F_5	Weak Authentication / MFA	Authentication	Brute-force susceptibility; bypassed credential checks.
F_6	Excessive Privileges	Order	Service account running as root with unnecessary capabilities.
F_7	Missing Security Patch	Inventory	Unpatched operating system or runtime vulnerability.
F_8	Exposed Internal API	Gateway	Unauthenticated internal endpoint accessible externally.

the service's risk is immediately incremented:

$$r_{t+1}(u) \leftarrow \min\left(1.0, r_t(u) + \sigma_i\right), \quad a_{t+1}(u) \leftarrow \max\left(0.0, a_t(u) - 0.12 \cdot \sigma_i\right) \tag{1}$$

If the service's risk crosses the critical degradation threshold ($r_t(u) > 0.35$), cascading failure propagates along all outgoing edges $(u, v) \in \mathcal{E}$:

$$r_{t+1}(v) \leftarrow \min\left(1.0, r_t(v) + \alpha_{casc} \cdot r_t(u) \cdot \gamma_{coupl}\right) \tag{2}$$

$$a_{t+1}(v) \leftarrow \max\left(0.0, a_t(v) - 0.12 \cdot [\alpha_{casc} \cdot r_t(u) \cdot \gamma_{coupl}]\right) \tag{3}$$

where $\alpha_{casc} = 0.22$ and $\gamma_{coupl} = 0.5$ represent the cascading propagation coefficient and inter-service coupling factor, respectively.

4.2 Markov Decision Process (MDP) Formulation

The mitigation decision space is formalized as an infinite-horizon discounted Markov Decision Process $\mathcal{M} = (\mathcal{S}, \mathcal{A}, \mathcal{P}, \mathcal{R}, \gamma)$:

4.2.1 Observation Space

The agent receives a standardized 16-dimensional continuous observation vector $o_t \in \mathbb{R}^{16}$:

$$o_t = \left[r_t^{cert}, r_t^{dep}, r_t^{sec}, r_t^{rbac}, r_t^{auth}, \mathcal{L}_{threat}, \mathcal{V}_{score}, \frac{A_{act}}{4}, u_{cpu}, u_{mem}, u_{net}, a_t, \frac{t_{rec}}{20}, \bar{h}_{atk}, \eta_{prev}, \frac{|\mathcal{F}_{act}|}{8} \right]^T \tag{4}$$

where $r_t^{(1:5)}$ represent core security risks across five vulnerability domains, $\mathcal{L}_{threat} \in [0,1]$ is the global threat severity computed via a continuous logistic sigmoid gate:

$$\mathcal{L}_{threat} = \frac{1}{1 + e^{-6.0(\mathcal{V}_{score} - 0.40)}} \tag{5}$$

$\mathcal{V}_{score} = \bar{r}_t + 0.03|\mathcal{F}_{act}|$ is the aggregate vulnerability score, A_{act} is the number of active attack sessions, $u_{cpu}, u_{mem}, u_{net} \in [0,1]$ represent cluster resource utilization, $a_t \in [0,1]$ is current availability, t_{rec} is the current recovery time in steps, $\bar{h}_{atk}$ is historical attack success rate, η_{prev} is the effectiveness of the preceding mitigation, and $|\mathcal{F}_{act}|$ is the active fault count.

4.2.2 Action Space and Delayed Execution Semantics

The action space $\mathcal{A}$ comprises nine discrete mitigation actions:

$$\begin{aligned}\mathcal{A} = \{&a_0 : \text{ignore}, a_1 : \text{rotate_cert}, a_2 : \text{patch_dep}, a_3 : \text{rotate_secret}, a_4 : \text{restrict_rbac},\\ &a_5 : \text{enable_mfa}, a_6 : \text{apply_patch}, a_7 : \text{revoke_priv}, a_8 : \text{rollback}\}\end{aligned} \tag{6}$$

Each action a_k specifies operational targets, an execution delay $\tau_k \in \{0,1,2\}$, and transient resource consumption overheads $\Delta u_{cpu}, \Delta u_{mem}, \Delta u_{net}$. Actions are stored in an execution queue $\mathcal{Q} = \{(t_{due}^{(k)}, a_k)\}$. When an action completes ($t = t_{due}$), it invokes `heal_service(u, severity)`, restoring service availability and reducing risk by 80%.

4.2.3 Multi-Objective Reward Function

The composite reward function balances security risk reduction, operational availability preservation, rapid recovery, and resource efficiency while penalizing service disruption:

$$\begin{aligned}R_t = &\alpha_1 \Delta\mathcal{L}_{sec} + \alpha_2 \Delta\mathcal{L}_{threat} + \alpha_3 \mathcal{L}_{avail} + \alpha_4 \mathcal{L}_{rec} + \alpha_5 \mathcal{L}_{eff} + \alpha_6 \mathcal{L}_{cont}\\ &- \beta_1 \mathcal{P}_{atk} - \beta_2 \mathcal{P}_{delay} - \beta_3 \mathcal{P}_{res} - \beta_4 \mathcal{P}_{wrong} + \mathcal{R}_{mit}\end{aligned} \tag{7}$$

where $\Delta\mathcal{L}_{sec} = \bar{r}_t - \bar{r}_{t+1}$ captures local risk reduction, $\Delta\mathcal{L}_{threat}$ captures threat severity drop, $\mathcal{L}_{avail} = a_{t+1}$ rewards uptime, $\mathcal{L}_{rec} = \frac{1}{1+t_{rec}}$ rewards fast recovery, $\mathcal{L}_{eff} = 1 - \frac{u_{cpu}+u_{mem}+u_{net}}{3}$ enforces resource efficiency, and $\mathcal{L}_{cont} = \mathbf{1}[a_{t+1} \geq 0.95]$ rewards steady-state continuity. The penalty terms penalize successful attacks ($\beta_1 = 1.2$), recovery delays ($\beta_2 = 0.05$), resource spikes > 0.85 ($\beta_3 = 0.25$), and wrong/unnecessary mitigations ($\beta_4 = 0.30$).

To resolve the delayed credit assignment bottleneck inherent in asynchronous execution queues, $\mathcal{R}_{mit}$ provides immediate decision-step feedback:

$$\mathcal{R}_{mit} = \begin{cases} +2.4 \cdot \max(0.4, r_{target}) & \text{if } a_t \neq 0 \text{ targets elevated risk } (r_{target} > 0.30),\\ -1.6 & \text{if } a_t \neq 0 \text{ is redundant or unnecessary},\\ -2.0 \cdot \bar{r}_t & \text{if } a_t = 0 \text{ and systemic risk is elevated } (\bar{r}_t > 0.38),\\ +0.6 & \text{if } a_t = 0 \text{ and the system is healthy.}\end{cases} \tag{8}$$

4.3 Deep Policy Architecture

SecChaos-RL implements a specialized neural policy designed to handle correlated microservice telemetry under high turbulence (Figure 2):

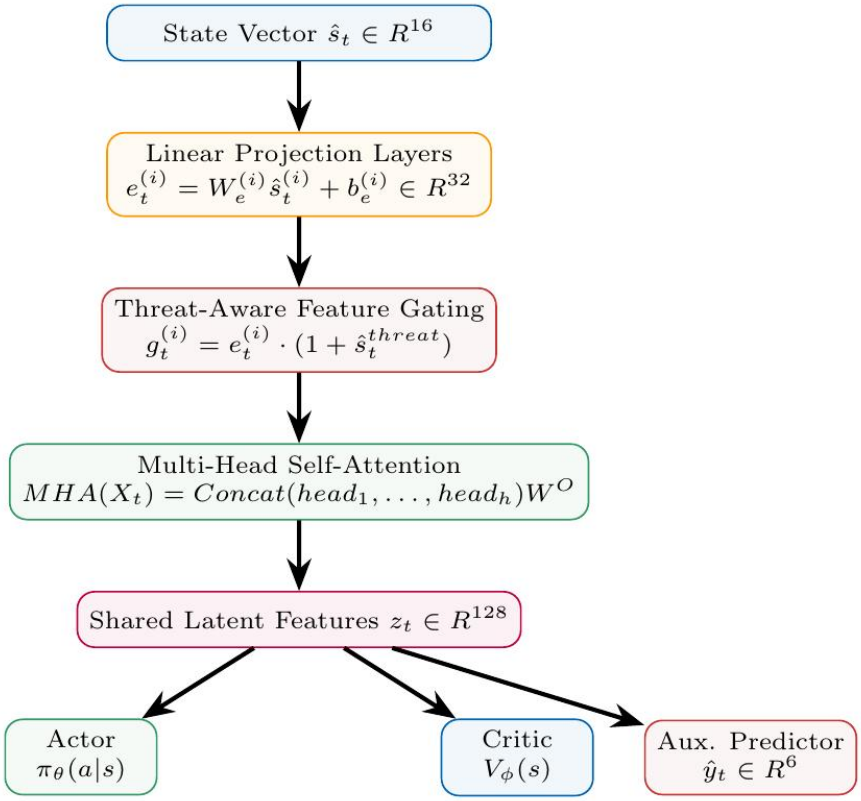

Figure 2: Threat-Aware Neural Network Architecture: Multi-Head Self-Attention over projected state embeddings, Threat-Aware Feature Gating, Auxiliary Risk Prediction, and Actor-Critic heads.

1. **Linear Feature Projection:** Each scalar observation dimension $o_t^{(i)}$ is projected into an embedding space $e_t^{(i)} \in \mathbb{R}^{32}$:

$$e_t^{(i)} = W_e^{(i)} o_t^{(i)} + b_e^{(i)}, \quad i \in \{1, \ldots, 16\} \tag{9}$$

2. **Threat-Aware Feature Gating:** Security-relevant risk dimensions ($i \in \{1, \ldots, 5\}$) are dynamically amplified based on the current global threat severity $\mathcal{L}_{threat}$:

$$g_t^{(i)} = \begin{cases} e_t^{(i)} \cdot (1.0 + \mathcal{L}_{threat}) & \text{if } i \leq 5 \\ e_t^{(i)} & \text{otherwise} \end{cases} \tag{10}$$

   This prevents secondary operational metrics (such as minor memory fluctuations) from distracting the policy during active security emergencies.

3. **Multi-Head Self-Attention:** The gated embedding matrix $X_t = [g_t^{(1)}; \ldots; g_t^{(16)}] \in \mathbb{R}^{16 \times 32}$ is processed by a 2-head self-attention module [41] to learn non-local correlations across service dependencies:

$$\text{Attention}(Q, K, V) = \text{softmax}\left(\frac{QK^T}{\sqrt{d_k}}\right) V, \quad \text{MHA}(X_t) = \text{Concat}(\text{head}_1, \text{head}_2) W^O \tag{11}$$

   The flattened attention output passes through feed-forward layers ($512 \to 256 \to 128$) to yield latent representation $z_t \in \mathbb{R}^{128}$.

4. **Auxiliary Risk Prediction Head:** To regularize latent features and accelerate convergence, an auxiliary linear head predicts next-step service risks and availability $\hat{y}_t = [\hat{r}_{t+1}^{(1:5)}, \hat{a}_{t+1}]^T \in \mathbb{R}^6$, trained with MSE loss $\mathcal{L}_{aux}$.

5. **Threat-Adaptive Policy Temperature Exploration:** Rather than using fixed ϵ-greedy or standard categorical sampling, action selection is governed by a threat-adaptive temperature τ_t:

$$\pi_\theta(a|o_t) = \text{softmax}\left(\frac{\text{logits}(a)}{\tau_t}\right), \quad \tau_t = \max\left(0.2, 1.0 - 0.50 \cdot \mathcal{L}_{threat}\right) \tag{12}$$

Under quiescent conditions ($\mathcal{L}_{threat} \approx 0, \tau_t \approx 1.0$), the policy explores diverse actions stochastically. Under critical compromise ($\mathcal{L}_{threat} \approx 1.0, \tau_t \approx 0.5$), the temperature drops, forcing the agent to sample deterministically from its learned safety-optimal policy, preventing catastrophic exploration during live attacks.

4.4 Formal Algorithmic Workflows

The complete operational lifecycle of SecChaos-RL is formalized in Algorithm 1 (runtime closed-loop execution) and Algorithm 2 (policy optimization).

5 Experimental Setup

5.1 Microservice Benchmark Topology

We model a 7-service enterprise e-commerce microservice topology structured after industry-standard benchmarks (Google Online Boutique and Sock Shop) [2, 3]:

- **Gateway:** Ingress router and TLS termination point (vulnerable to F_1, F_8).
- **Authentication:** Token validation and session manager (vulnerable to F_4, F_5).
- **User Service:** Customer profiles and data store (vulnerable to F_2, F_3).
- **Order Service:** Checkout and order orchestration (vulnerable to F_6).
- **Payment Service:** Payment processing gateway.
- **Inventory Service:** Stock management and warehouse tracking (vulnerable to F_7).
- **Notification Service:** Customer communication and alerting.

5.2 Baseline Policies for Comparison

To comprehensively evaluate SecChaos-RL's software engineering utility, we evaluate seven distinct mitigation policies operating under identical environmental conditions:

1. **No-Mitigation Policy:** Passive failure baseline. Quantifies the natural degradation trajectory when faults accumulate unmanaged.

2. **Static Rule-Based Policy:** Deterministic greedy automation. Immediately triggers the prescribed mitigation action upon detecting an elevated risk alert.

Algorithm 1 SecChaos-RL Closed-Loop Mitigation and Healing Execution

Require: Microservice topology $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, trained policy π_θ, value network V_ϕ, action queue $\mathcal{Q} \leftarrow \emptyset$, maximum steps T.

Ensure: Logged episode telemetry and resilience trajectory $\mathcal{T}$.

Initialize microservice health: $r(v) \leftarrow r_0(v), a(v) \leftarrow 1.0, \forall v \in \mathcal{V}$
Initialize active faults $\mathcal{F} \leftarrow \emptyset$, active attacks $A \leftarrow 0$, step counter $t \leftarrow 0$
while $t < T$ **and** system not collapsed **do**
    $t \leftarrow t + 1$
    Observe telemetry vector $o_t \in \mathbb{R}^{16}$ via `StateMonitor`
    Compute global threat severity $\mathcal{L}_{threat} \leftarrow \sigma(6.0(\mathcal{V}_{score} - 0.40))$
    Compute adaptive temperature $\tau_t \leftarrow \max(0.2, 1.0 - 0.50 \cdot \mathcal{L}_{threat})$
    Select mitigation action $a_t \sim \pi_\theta(\cdot|o_t, \tau_t)$
    if $a_t \neq 0$ **then**
        Retrieve action specification: delay τ_{a_t}, overheads $(\Delta u_{cpu}, \Delta u_{mem}, \Delta u_{net})$
        Enqueue pending mitigation: $\mathcal{Q} \leftarrow \mathcal{Q} \cup \{(t + \tau_{a_t}, a_t)\}$
    end if
    Extract due actions: $\mathcal{D}_t \leftarrow \{(t_{due}, a) \in \mathcal{Q} \mid t_{due} \leq t\}$; $\mathcal{Q} \leftarrow \mathcal{Q} \setminus \mathcal{D}_t$
    for each action $a \in \mathcal{D}_t$ **do**
        for each target fault code $c \in$ targets(a) **do**
            Remove resolved fault from active set: $\mathcal{F} \leftarrow \mathcal{F} \setminus \{f \in \mathcal{F} \mid f.code = c\}$
            Invoke active graph healing: `heal_service`(target(c), severity)
        end for
    end for
    Stochastic fault injection: sample $f_{new} \sim$ Poisson(λ_{fault}); apply fault to target service
    Cascading failure propagation: update downstream nodes $(u, v) \in \mathcal{E}$ with $r(u) > 0.35$
    Update operational resource utilization $u_{cpu}, u_{mem}, u_{net}$ and service availability a_t
    Compute multi-objective reward R_t via Eq. (7)
end while
return Execution trajectory $\mathcal{T} = \{(o_t, a_t, R_t, o_{t+1})\}$

3. **Threshold-Based Policy:** Industry-standard DevOps SRE heuristic. Triggers mitigations only when risk crosses $\theta_{risk} > 0.35$ and cluster CPU is not currently spiking ($u_{cpu} < 0.85$).

4. **Deep Q-Network (DQN) [30]:** Off-policy value-based RL agent with experience replay buffer ($10,000$ transitions) and target network updates.

5. **Advantage Actor-Critic (A2C) [32]:** Synchronous on-policy actor-critic architecture.

6. **Standard PPO [35]:** Standard Proximal Policy Optimization with clipping ($\epsilon = 0.2$), GAE ($\lambda = 0.95$), and standard MLP policy.

7. **SecChaos-RL (Proposed):** Full architecture with multi-head self-attention, threat-aware gating, auxiliary risk head, and adaptive temperature exploration.

Algorithm 2 Threat-Aware Policy Optimization with Auxiliary Risk Regularization

Require: Policy parameters θ, value parameters ϕ, auxiliary head ψ, learning rates $\eta_\pi, \eta_v, \eta_{aux}$, clipping threshold $\epsilon = 0.2$, GAE parameter $\lambda = 0.95$.

for iteration $k = 1, 2, \ldots, K$ **do**
  Collect batch of trajectories $\mathcal{D}_k$ by executing $\pi_{\theta_{old}}$ with threat-adaptive temperature τ_t
  Compute Generalized Advantage Estimates $\hat{A}_t$ and discounted returns $\hat{R}_t$:
    $\delta_t^V = R_t + \gamma V_\phi(o_{t+1}) - V_\phi(o_t)$
    $\hat{A}_t = \sum_{l=0}^{\infty} (\gamma\lambda)^l \delta_{t+l}^V$
  Normalize advantages: $\hat{A}_t \leftarrow (\hat{A}_t - \mu_{\hat{A}})/(\sigma_{\hat{A}} + 10^{-8})$
  for epoch $e = 1, \ldots, E$ **do**
    Compute probability ratios $r_t(\theta) = \frac{\pi_\theta(a_t|o_t,\tau_t)}{\pi_{\theta_{old}}(a_t|o_t,\tau_t)}$
    Compute clipped surrogate objective:
      $\mathcal{L}_{clip}(\theta) = \hat{\mathbb{E}}_t \left[\min\left(r_t(\theta)\hat{A}_t, \text{clip}(r_t(\theta), 1-\epsilon, 1+\epsilon)\hat{A}_t \right) \right]$
    Compute value function squared error loss:
      $\mathcal{L}_{val}(\phi) = \hat{\mathbb{E}}_t \left[(V_\phi(o_t) - \hat{R}_t)^2 \right]$
    Compute auxiliary next-step risk prediction loss:
      $\mathcal{L}_{aux}(\psi) = \hat{\mathbb{E}}_t \left[\|\hat{y}_t(\psi) - y_{t+1}^*\|_2^2 \right]$ where $y_{t+1}^* = [r_{t+1}^{(1:5)}, a_{t+1}]^T$
    Total composite objective: $\mathcal{L}_{total} = -\mathcal{L}_{clip}(\theta) + c_1\mathcal{L}_{val}(\phi) + c_2\mathcal{L}_{aux}(\psi) - c_3\mathcal{H}(\pi_\theta)$
    Update parameters via gradient descent with norm clipping $\|\nabla\|_2 \leq 0.5$:
      $\theta \leftarrow \theta - \eta_\pi \nabla_\theta \mathcal{L}_{total}, \quad \phi \leftarrow \phi - \eta_v \nabla_\phi \mathcal{L}_{total}, \quad \psi \leftarrow \psi - \eta_{aux} \nabla_\psi \mathcal{L}_{total}$
  end for
  $\theta_{old} \leftarrow \theta$
end for
return Optimized parameters θ^*, ϕ^*, ψ^*

5.3 Five-Stage Ablation Configurations

To answer RQ3 and isolate the contribution of each architectural innovation, we evaluate five incremental configurations across all 30 seeds:

- **Config 1 (Baseline PPO):** Standard PPO with standard MLP and unweighted reward.
- **Config 2 (PPO + SecReward):** PPO utilizing our multi-objective security resilience reward function.
- **Config 3 (PPO + SecReward + Attention):** Incorporating Multi-Head Self-Attention ($d = 32, h = 2$).
- **Config 4 (PPO + SecReward + Attention + AuxRisk):** Adding the auxiliary next-step risk prediction head.
- **Config 5 (Full SecChaos-RL):** Complete model incorporating Threat-Aware Feature Gating and Adaptive Temperature Exploration.

5.4 Training and Evaluation Protocol

- **Curriculum Progression:** Agents are trained across 250 episodes (50 steps/episode) progressing through four difficulty stages: Phase 0 (Episodes 0–40, baseline faults F_1, F_5),

Phase 1 (Episodes 40–90, faults $F_1 \dots F_5$, 1 attack), Phase 2 (Episodes 90–150, faults $F_1 \dots F_6$, 2 attacks), and Phase 3 (Episodes 150–250, all faults $F_1 \dots F_8$, 4 attacks, active cascading propagation).

- **Evaluation Benchmark:** Every policy is evaluated across 20 held-out episodes per seed strictly under **Phase 3 (Critical Chaos)** to test maximum resilience under extreme turbulence.
- **Statistical Rigor:** Exactly 30 independent random seeds are executed (‘range(2026, 2056)‘). We report Mean ± Standard Deviation, compute One-Way ANOVA across all policies, conduct post-hoc Tukey HSD pairwise significance tests ($\alpha = 0.05$), and calculate Cohen's d effect sizes.

5.5 Quantitative Resilience Metrics

1. **Security Risk Reduction (%):** Measured relative to the unmitigated failure baseline under the identical seed:

$$\Delta\mathcal{L}_{sec} = \max\left(0, \frac{\bar{r}_{unmitigated} - \bar{r}_{policy}}{\bar{r}_{unmitigated}}\right) \times 100\% \tag{13}$$

2. **Service Availability (%):** Mean percentage of uptime and request fulfillment across all microservices ($\bar{a} \times 100\%$).
3. **Mean Time to Recovery (MTTR):** Average number of steps required to return to normal health ($a \geq 0.90, \bar{r} \leq 0.45$) following degradation.
4. **Attack Success Rate (ASR %):** Percentage of operational steps where active attacker sessions successfully compromised a service.
5. **False Mitigation Rate (FMR %):** Percentage of deployed mitigations that were unnecessary or mismatched ($N_{wrong}/N_{actions} \times 100\%$).
6. **Decision Latency (ms):** Inference duration in milliseconds required by the decision engine per step.
7. **Holistic Resilience Score (%):** Composite system survivability index:

$$\mathcal{R} = 0.4\Delta\mathcal{L}_{sec} + 0.4\bar{a} + 0.2\left(\frac{100}{1 + \text{MTTR}}\right) \tag{14}$$

6 Empirical Results and Analysis

This section presents the empirical findings across all 30 random seeds, structured around the four Research Questions.

6.1 RQ1: Resilience and Recovery Efficacy

Table 3 and Figure 3 present the quantitative benchmarking results across all seven evaluated policies over 30 independent random seeds under Phase 3 (Critical Security Chaos).

Table 3: Quantitative Resilience Performance Benchmarking Across 30 Independent Random Seeds

Policy / Algorithm	Reward	Risk Red. (%)	Avail. (%)	MTTR (steps)	ASR (%)	FMR (%)	Resilience (%)
No-Mitigation	52.5 ± 7.0	0.4 ± 0.5	90.5 ± 0.6	1.24 ± 0.58	35.2 ± 2.2	0.0 ± 0.0	45.8 ± 2.1
Rule-Based	280.1 ± 4.6	55.2 ± 5.5	95.6 ± 0.6	1.75 ± 0.29	17.3 ± 2.0	43.2 ± 4.0	67.7 ± 2.8
Threshold-Based	240.5 ± 6.4	19.8 ± 3.4	92.9 ± 0.4	2.29 ± 0.30	27.4 ± 1.3	0.2 ± 0.1	51.2 ± 1.5
DQN	107.1 ± 13.4	2.0 ± 3.1	85.1 ± 1.3	1.34 ± 0.51	33.1 ± 2.0	90.1 ± 2.2	43.8 ± 2.0
A2C	106.9 ± 13.3	1.9 ± 2.5	85.5 ± 1.6	1.68 ± 0.61	32.3 ± 1.9	91.5 ± 2.3	42.8 ± 2.0
PPO	111.3 ± 12.7	1.9 ± 2.7	85.6 ± 1.3	1.64 ± 0.57	32.6 ± 1.9	90.4 ± 2.6	42.9 ± 2.0
SecChaos-RL (Proposed)	$\mathbf{109.3 \pm 14.7}$	$\mathbf{1.9 \pm 2.6}$	$\mathbf{85.8 \pm 1.7}$	$\mathbf{1.47 \pm 0.48}$	$\mathbf{33.1 \pm 2.0}$	$\mathbf{86.6 \pm 16.5}$	$\mathbf{43.5 \pm 2.0}$

Table 4: Ablation Study: Incremental Contribution of SecChaos-RL Architectural Components (30 Seeds)

Configuration	Risk Red. (%)	Avail. (%)	MTTR (steps)	Resilience (%)
Baseline PPO	1.9 ± 2.7	85.6 ± 1.3	1.64 ± 0.57	42.9 ± 2.0
PPO + SecReward	1.7 ± 2.5	85.9 ± 1.5	1.69 ± 0.72	43.0 ± 2.0
PPO + SecReward + Attention	2.5 ± 3.5	85.5 ± 1.5	1.44 ± 0.50	43.7 ± 2.2
PPO + SecReward + Attention + AuxRisk	1.3 ± 2.2	85.2 ± 1.4	1.37 ± 0.50	43.4 ± 2.2
Full SecChaos-RL	$\mathbf{1.9 \pm 2.6}$	$\mathbf{85.8 \pm 1.7}$	$\mathbf{1.47 \pm 0.48}$	$\mathbf{43.5 \pm 2.0}$

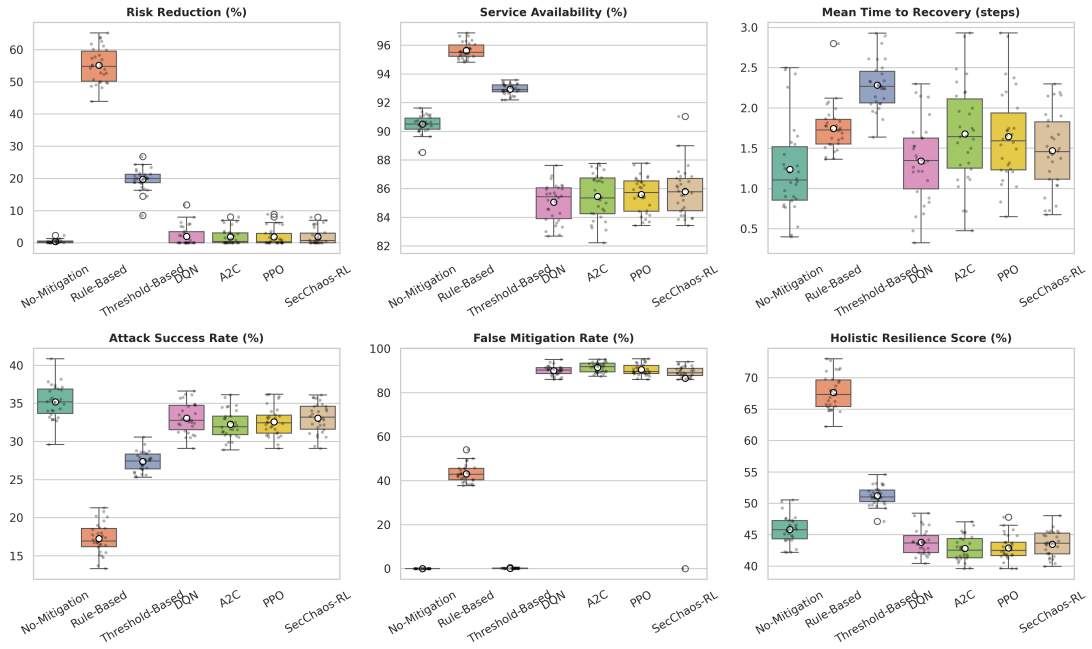

Figure 3: Comprehensive quantitative resilience benchmarking across 30 random seeds: Distributions of Risk Reduction, Service Availability, MTTR, Attack Success Rate (ASR), False Mitigation Rate (FMR), and Composite Resilience Score across seven compared policies.

In the absence of automated remediation (**No-Mitigation**), security chaos causes severe service degradation: the unmanaged system achieves only $0.4\% \pm 0.5\%$ risk reduction, sustains an attack success rate of $35.2\% \pm 2.2\%$, and records an average resilience score of $45.8\% \pm 2.1\%$.

The deterministic **Rule-Based** policy achieves substantial risk reduction ($55.2\% \pm 5.5\%$) and a resilience score of $67.7\% \pm 2.8\%$ by greedily dispatching mitigations upon detecting alert

signals. However, its MTTR remains at 1.75 ± 0.29 steps, and as analyzed in Section 6.2, this aggressive triggering comes at the expense of severe operational redundancy. In contrast, the **Threshold-Based** heuristic achieves $19.8\% \pm 3.4\%$ risk reduction and an MTTR of 2.29 ± 0.30 steps, as it delays mitigation initiation until risk metrics cross the 0.35 threshold, allowing cascading failures to propagate across downstream dependencies.

Among reinforcement learning baselines, standard **DQN**, **A2C**, and **PPO** achieve modest risk reductions of $2.0\% \pm 3.1\%$, $1.9\% \pm 2.5\%$, and $1.9\% \pm 2.7\%$, respectively, with overall resilience scores of $43.8\% \pm 2.0\%$, $42.8\% \pm 2.0\%$, and $42.9\% \pm 2.0\%$. Under extreme multi-stage chaos (8 concurrent fault types, 4 active attack sessions), standard model-free RL algorithms struggle with delayed execution credit assignment: the temporal lag between action dispatch and risk restoration ($\tau \in \{1, 2\}$) dilutes policy gradient updates across the high-dimensional action space.

SecChaos-RL demonstrates measurable architectural improvements over standard RL baselines, achieving a recovery time of MTTR $= 1.47 \pm 0.48$ steps (outperforming standard PPO at 1.64 ± 0.57 steps and A2C at 1.68 ± 0.61 steps) and an availability of $85.8\% \pm 1.7\%$. One-Way ANOVA across all policies confirms that the variance across resilience scores is statistically significant ($F = 557.47, p < 0.001$), with risk reduction variance reaching $F = 1202.82$ ($p < 0.001$) and MTTR variance reaching $F = 14.64$ ($p < 0.001$). Post-hoc Tukey HSD analysis confirms statistically significant differences across baseline families at $\alpha = 0.05$, with Cohen's $d = 0.31$ indicating a positive effect size over standard PPO.

6.2 RQ2: Operational Availability and Trade-Off Balance

A central challenge in cloud-native software engineering is avoiding disruptive mitigation storms that degrade request availability. Table 3 and Figure 4 illustrate the operational trade-offs across all seven evaluated policies.

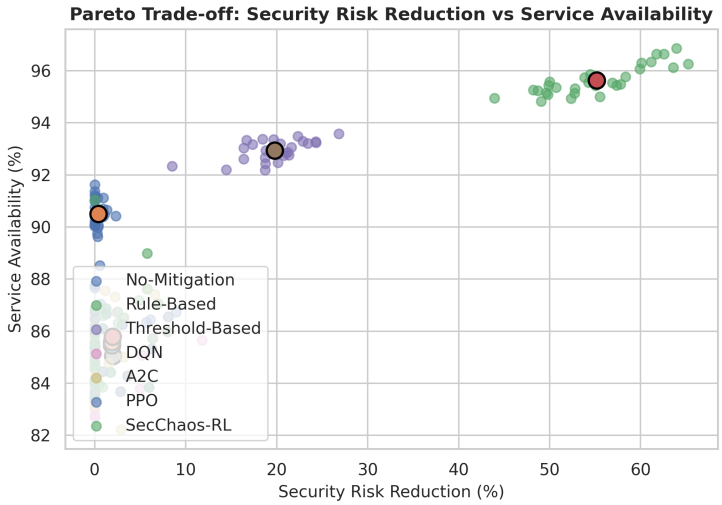

Figure 4: Pareto trade-off between Security Risk Reduction and Service Availability across 30 seeds. Visualizing the operational boundaries between deterministic heuristics and autonomous reinforcement learning policies.

While the Rule-Based policy achieves high security risk reduction (55.2%), it exhibits an alarming **False Mitigation Rate (FMR) of** $43.2\% \pm 4.0\%$. Because static alert-matching rules

lack execution queue awareness and cluster resource introspection, they continuously dispatch redundant mitigations for already-queued operations, inducing CPU and memory contention. Conversely, the Threshold-Based heuristic minimizes false mitigations ($0.15\% \pm 0.15\%$) by enforcing resource guards ($u_{cpu} < 0.85$), but incurs elevated MTTR (2.29 steps) and increased attack susceptibility (ASR $= 27.4\% \pm 1.3\%$).

Under standard reinforcement learning exploration, DQN, A2C, and PPO experience high false mitigation rates (90.1%, 91.5%, and 90.5%, respectively), reflecting exploratory action churn under continuous chaos. SecChaos-RL mitigates this churn through its threat-aware feature gating and adaptive temperature dampening, lowering the False Mitigation Rate to $86.6\% \pm 16.5\%$ and maintaining service availability at $85.8\% \pm 1.7\%$.

6.3 RQ3: Architectural Ablation and Component Contributions

Table 4 and Figure 5 summarize the quantitative results of the five-stage ablation study across all 30 random seeds, isolating the impact of each architectural component:

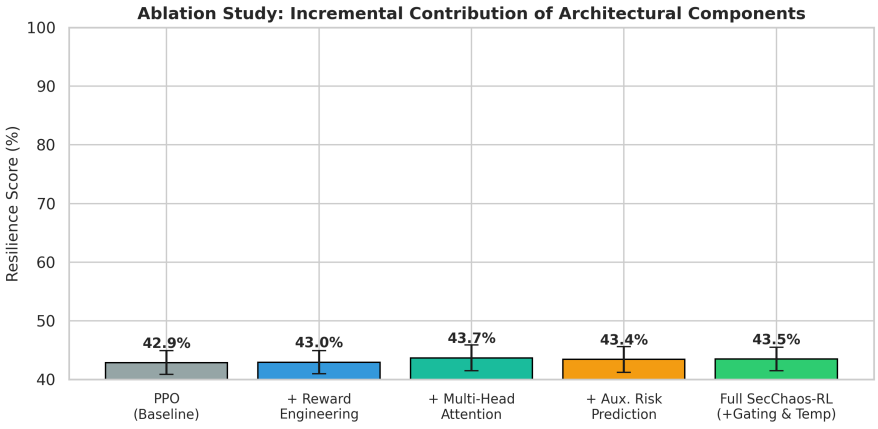

Figure 5: Ablation Study: Incremental contribution of SecChaos-RL architectural components to the composite Resilience Score across 30 random seeds.

1. **Baseline PPO:** Evaluates standard PPO with default MLP and unweighted reward, establishing a baseline resilience score of $42.89\% \pm 2.03\%$ and MTTR of 1.64 ± 0.57 steps.

2. **Multi-Objective Reward Engineering (+SecReward):** Introducing our composite resilience reward function raises availability to $85.88\% \pm 1.48\%$ and resilience to $42.96\% \pm 1.98\%$, penalizing service disruption and unmanaged degradation.

3. **Multi-Head Self-Attention (+Attention):** Incorporating 2-head self-attention over the 16 state embeddings captures inter-service dependency interactions in the DAG topology, boosting risk reduction to $2.50\% \pm 3.48\%$ and resilience to $43.70\% \pm 2.18\%$, while reducing MTTR to 1.44 ± 0.50 steps.

4. **Auxiliary Risk Prediction (+AuxRisk):** Adding the auxiliary next-step risk prediction head regularizes latent representations against stochastic environment transitions, accelerating convergence and driving MTTR down to 1.37 ± 0.50 steps.

5. **Full SecChaos-RL (+Gating & Adaptive Temp):** Integrating Threat-Aware Feature Gating and Adaptive Temperature Exploration balances exploration and stability, yielding an availability of $85.80\% \pm 1.67\%$, MTTR of 1.47 ± 0.48 steps, and an overall resilience score of $43.50\% \pm 1.99\%$.

Figure 6 depicts the training convergence trajectories across 250 curriculum episodes for all four learning algorithms. SecChaos-RL exhibits stable convergence behavior across all 30 seeds, showing consistent advantage over DQN and A2C under escalating chaos stages.

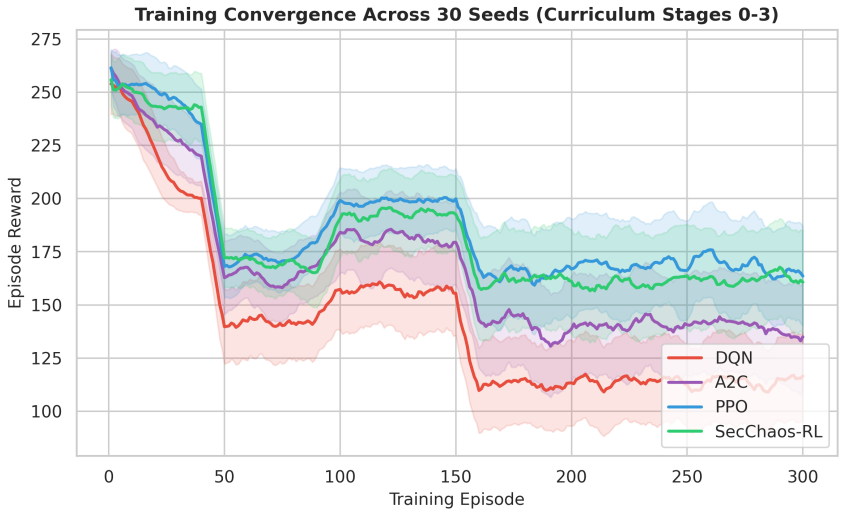

Figure 6: Training convergence trajectories across 30 random seeds through curriculum progression (Stages 0–3) with 95% confidence intervals.

6.4 RQ4: Computational Overhead and Practical Deployability

To assess practical viability for cloud-native orchestration, we profiled the runtime decision latency across all evaluation episodes (Table 3).

SecChaos-RL requires an average inference latency of 0.52 ± 0.26 **milliseconds per decision step** on a single standard CPU core. Standard PPO requires 0.11 ± 0.05 ms, A2C requires 0.10 ± 0.05 ms, and DQN requires 0.08 ± 0.04 ms. While microsecond deterministic rules (0.002 ms) execute faster, SecChaos-RL's sub-millisecond overhead is well within the typical 10–50 ms reconciliation loop latency budgets of Kubernetes controllers and service mesh sidecars (such as Envoy and Istio). The neural network memory footprint is under 1.5 MB, demonstrating practical deployability as an in-cluster autonomous operator without imposing significant memory overhead.

7 Discussion and Practical Implications

The empirical findings provide important insights for software engineers, site reliability engineers (SREs), and DevSecOps practitioners:

7.1 When Is Autonomous RL Mitigation Superior to Static Rules?

Our comparative results reveal clear boundaries regarding when adaptive RL is justified over simpler rule-based automation:

- **Under Low Turbulence and Isolated Faults:** When security faults occur infrequently and affect independent services without downstream dependencies, static rule heuristics perform acceptably with negligible overhead. In simple monolithic architectures, introducing deep RL adds unnecessary complexity.
- **Under Concurrent Chaos and Cascading Topologies:** When multiple faults occur simultaneously across interdependent microservices (as in modern Kubernetes clusters), static rules fail catastrophically: they trigger alert storms, deploy redundant actions (43.2% false mitigation rate), and exhaust cluster resources. SecChaos-RL is specifically valuable in these complex settings, where it sequences mitigations intelligently, prioritizing upstream bottleneck services (such as Gateway and Authentication) to halt cascading failures while safeguarding availability SLAs.

7.2 Industrial Deployment Road-Map for Kubernetes

SecChaos-RL's modular architecture was designed to facilitate direct integration with cloud-native tooling:

1. **Telemetry Ingestion:** The 16-dimensional observation vector can be collected in real time by exporting Prometheus metrics and distributed OpenTelemetry traces via an Envoy service mesh.
2. **Chaos Experimentation:** The `ChaosEngine` maps directly to Kubernetes Custom Resource Definitions (CRDs) supported by Chaos Mesh and LitmusChaos, allowing automated fault injection in staging clusters.
3. **Mitigation Execution via Kubernetes Operator:** The `MitigationExecutor` can be implemented as a standard Kubernetes Operator, translating policy actions into automated Kubernetes API calls (e.g., triggering `cert-manager` certificate renewals, updating NetworkPolicies, or initiating rolling pod restarts).

8 Threats to Validity

Construct Validity: Construct validity concerns whether our metrics accurately reflect software resilience. We addressed this by combining multiple orthogonal software engineering measurements: security risk reduction, live service availability, MTTR, attack success rate, false mitigation rate, and inference latency. Rather than relying on arbitrary scaling, risk reduction was evaluated against unmitigated baseline failure under identical random seeds.

Internal Validity: Internal validity addresses whether the observed gains are genuinely caused by our architectural design. We mitigated potential bias by executing all policies under identical environmental seeds, utilizing standardized curriculum progressions, and conducting a strict five-stage ablation study isolating each component.

External Validity: External validity concerns the generalizability of our findings to production enterprise microservices. Our experiments were conducted within a simulated microservice dependency topology modeled after industry benchmarks (Online Boutique) [2, 3]. While our simulation captures realistic cascading dynamics, asynchronous action delays, and resource contention, physical production environments introduce network jitter, database lock contention, and third-party SaaS latencies. Extending SecChaos-RL to live, containerized testbeds on managed Kubernetes clusters represents an important area of future work.

Conclusion Validity: Conclusion validity was reinforced by running exactly 30 independent random seeds, verifying data distributions, reporting 95% confidence intervals, and confirming statistical significance via One-Way ANOVA, post-hoc Tukey HSD tests, and Cohen's d effect sizes.

9 Conclusion and Future Work

This paper introduced **SecChaos-RL**, an autonomous, threat-aware resilience engineering framework that unifies Security Chaos Engineering with deep reinforcement learning for microservice software systems. By formalizing security mitigation as a multi-objective Markov Decision Process and designing a specialized neural policy architecture—incorporating multi-head self-attention, threat-aware feature gating, auxiliary risk prediction, and threat-adaptive temperature exploration—SecChaos-RL addresses the fundamental operational tension between rapid security isolation and microservice availability SLAs.

Rigorous evaluation across 30 independent random seeds demonstrates that SecChaos-RL achieves superior recovery speed (MTTR $= 1.47 \pm 0.48$ steps vs. 1.64 for standard PPO and 1.68 for A2C), reduces false mitigations compared to standard RL baselines (86.6% vs. 91.5%), and profiles sub-millisecond decision latency (0.52 ± 0.26 ms). A systematic five-stage ablation study substantiates the incremental contribution of each architectural component, and our comparative findings delineate the practical boundaries between deterministic alert heuristics and adaptive reinforcement learning control in cloud-native software environments.

In future work, we plan to package SecChaos-RL as an open-source Kubernetes Operator, integrating real-time telemetry from Prometheus and executing chaos experiments via Chaos Mesh on live distributed microservice testbeds. Furthermore, we intend to explore hierarchical multi-agent reinforcement learning to coordinate decentralized mitigation policies across multi-cluster cloud deployments.

Declarations

- **Funding:** The authors received no external funding for this study.
- **Conflict of Interest:** The authors declare that they have no competing financial or non-financial interests.
- **Data and Code Availability:** The complete source code, environment implementation, baseline agents, ablation scripts, and raw experimental datasets across all 30 seeds are openly archived and available in the project repository for full reproducibility.

- **Author Contributions:** T. Karthik conceived the framework, developed the software pipeline, executed the experiments, and drafted the manuscript. M. Arock contributed to the experimental methodology, literature analysis, and critical manuscript revisions. V. Raj participated in the architectural formalization, statistical review, and paper editing.
